15 **Introduction**

16 The prevalence of anaemia in pregnant women [1] and in children [2] remains unacceptably high in
17 remote Northern Territory (NT) Aboriginal communities despite prevention strategies that have
18 been in place for nearly a decade [3-5]. Children in these communities are unique within the broader
19 Australian population, with a greater exposure to infection [6] and higher rates of undernutrition
20 underpinned by economic and social disadvantage [7].

21

22 Surveillance data from 2015 reported 17% prevalence of anaemia in children aged under five years,
23 with the highest prevalence of 34% in children aged 12-17 months [2]. Recently published data from
24 six remote communities across Northern Australia identified that 42% of children had an anaemic
25 episode in the first two years of life [8]. Identification of the cause of anaemia is not routinely
26 conducted in children as it was previously assumed that all anaemia was iron deficiency (9).

27

28 No studies have identified risk factors for the development of childhood anaemia in remote
29 Aboriginal communities (10). Local best practice guidelines, Central Australian Rural Practitioners
30 Association standard treatment manual (CARPA STM), acknowledge the role of prematurity and low
31 birth weight (LBW) as risk factors for the development of anaemia and recommend routine iron
32 supplementation from one month of age [9].

33

34 A growing body of evidence from international literature that suggests maternal anaemia in
35 pregnancy is an independent risk factor for infant anaemia and iron deficiency [10-14]. The

1 increased risk of developing anaemia is detectable as early as 3-5 months of age [11] and may persist
2 up to 56 months [14]. Exclusive breastfeeding without iron supplementation or early introduction of
3 iron rich weaning foods appears to exacerbate the risk of iron deficiency anaemia (IDA) [12].

4
5 Although limited by a lack of reliable data, there is a high prevalence of maternal anaemia in
6 pregnancy in remote communities in the NT with estimates between 14-50% [1, 15]. Maternal
7 anaemia may represent an important and under recognised risk factor for the development of
8 childhood anaemia. If maternal anaemia in pregnancy is proven to be a risk factor, early
9 identification and treatment may provide an upstream point of intervention in the prevention of
10 childhood anaemia.

11
12 This study aims to identify maternal and perinatal risk factors associated with childhood anaemia to
13 identify children who are at increased risk. Identification of children at risk will enable more effective
14 targeted strategies of prevention and early intervention. Linking maternal and child data provided a
15 longitudinal view of each child for the first 1000 days from conception to two years of age.

16 17 **Methods**

18 *Study setting:* This study was part of the Sunrise Anaemia Project, a broader investigation of a
19 childhood anaemia program in remote communities in Katherine East region, NT. The project was
20 instigated by Sunrise Health Service, an Aboriginal community-controlled health organisation, who
21 consented to be identified. Three communities were included: A, B and C, with populations ranging
22 from ~300-1000 and with ~260 births during the study period (data from communications with
23 Sunrise Health Data Integrity Officer).

24
25 Katherine region is located in the tropical region of Australia (23.5° South) that has a wet (October-
26 March) and dry (April-September) season. All three communities are accessible by road in the dry
27 season but during the wet season two of the communities are often only accessible by air [16].

28 Health care is provided by Remote Area Nurses and/or Midwives (RAN/Ms), Aboriginal Health
29 Practitioners (AHPs), visiting Medical Officers and Allied Health Professionals.

30
31 *Study design and participants:* A retrospective cohort study design was used to report on the
32 outcome of anaemia at different ages. Children enrolled were born between 1 January 2004 and 31
33 December 2014 in Community A and 1 January 2010 to 31 December 2014 in Community B and C,
34 along with their respective mothers. Each child's primary healthcare (PHC) presentations for the first

1 two years of life and maternal antenatal records that were associated with that child were extracted
2 from the electronic health record system (Communicare). The Communicare data was exported as a
3 CSV file and imported to StataCorp14.1 (Statacorp, College Station, Texas) for cleaning, linkage and
4 analysis. Clinical notes and pathology results were manually reviewed to identify and include missing
5 data that was not included in the initial electronic data extraction.

6

7 *Ethics:* Ethics approval was attained through Human Research Ethics Committee of Northern
8 Territory Department of Health and Menzies School of Health Research (EC00153), reference
9 number 2015-2525. Written informed consent was obtained from all participants or their
10 responsible adult guardian.

11 *Data collection:* Maternal antenatal data extracted from the electronic health records included: date
12 of visit, age, parity, haemoglobin (Hb), iron treatment (oral or parenteral), laboratory (full blood
13 count and iron studies) and ultrasound results. Data was not available for maternal diet during
14 pregnancy or smoking history. Hb was measured in communities by point of care testing using
15 capillary blood in a HemoCue machine, or from a venous blood sample sent to a diagnostic
16 laboratory for full blood count and/or iron studies. HemoCue testing has been validated as a
17 suitable instrument for anaemia screening with a mean Hb difference of 0.8 g/L compared to
18 the commonly used laboratory methods [17].

19

20 Child data collected included: sex, birthweight and gestational age at birth, date of child health check
21 visit, Hb measured by Hemocue, full blood count or iron studies. Scheduled health checks at six, 12,
22 18 and 24 months for measurement of Hb included results conducted either two months prior or
23 post the age scheduled check.

24

25 Outcome and risk factor parameters were identified from local best practice guidelines: CARPA STM
26 [9] and Women's Business Manual (WBM) [18] (Table 1).

27

28 **Table 1. Variables definitions**

<i>Risk factors</i>	
Maternal anaemia	Hb <110 g/L
Premature	Born before 37 completed weeks gestation
Low birthweight	Birthweight <2.5 kg

<i>Outcomes</i>	
Childhood anaemia	Hb <105 g/L if aged 6–11 months Hb <110 g/L if aged 1-2 years
Severe anaemia	Hb <90g/L

29

1 *Case Definitions:* IDA was determined from a full blood count that was microcytic (mean corpuscular
2 volume <75 fL) and hypochromic (mean corpuscular haemoglobin concentration <310 g/L). If iron
3 studies were performed, IDA was diagnosed if ferritin was <12 mcg/L in children and <30 mcg/L in
4 pregnant women.

5 Iron treatment was defined as: evidence of oral or parenteral iron in the prescriptions variable or
6 documentation of iron administered in the progress notes of the extracted Communicare data.

7
8 Data analysis: Data from the three communities were pooled as baseline characteristics were
9 homogenous throughout. Descriptive analyses were used to calculate mean maternal age, and
10 proportions were used to describe other antenatal and perinatal characteristics of the mother/child
11 dyads. Pregnancy trimesters were categorised into first (≤ 12 weeks gestation), second (13-27 weeks)
12 and third (≥ 28 weeks). A scatterplot was used to test the linear relationship between maternal Hb
13 g/L in the third trimester of pregnancy and infant Hb g/L at age 6-months. R-squared >0.4 was
14 considered a strong association [19]. Anaemic mothers were stratified into two groups based on
15 whether they had received iron treatment during the third trimester of pregnancy. Univariate
16 logistic regression analysis was used to determine any association between childhood anaemia at
17 each age and maternal anaemia in pregnancy, LBW and prematurity. Outcomes were defined as
18 anaemia at six, 12, 18 and 24 months. A p-value < 0.05 was used as a threshold for statistical
19 significance for all tests.

21 **Results**

22 One hundred and ninety-six mother/child dyads were recruited across the three communities. One-
23 hundred and seventy were included for analysis after excluding 22 children born outside of the study
24 period and four not usually residing in one of the three communities. There were 75 (44%) male and
25 95 (56%) female children records linked to maternal antenatal records that represented 65% of
26 births during the study period.

27
28 The mean maternal age during pregnancy was 23.6 years with almost two thirds ($n = 107$, 63%) of
29 women having two or more children (Table 2). All women had singleton pregnancies of which 42
30 (25%) were LBW and 35 (21%) were premature.

31

<i>Birth details</i>				
Term and ≥2.5 kg	49 (74)	44 (67)	25 (66)	118 (69)
Low birth weight (<2.5kg)	14 (21)	19 (29)	9 (24)	42 (25)
Premature (<37 weeks)	10 (15)	13 (20)	12 (32)	35 (21)

2

3 Anaemia screening was documented in all 170 pregnancies in the third trimester but occurred less
 4 frequently in the first (n = 70, 41%) and second trimesters (n= 50, 29%) (Table 3). Taking into
 5 consideration the delayed presentation to antenatal care, 119 (70%) women were screened for
 6 anaemia at their first visit.

7

8 Almost half of the women tested in the first (n=32, 46%) and second (n=24, 48%) trimester of
 9 pregnancy were anaemic, this increased in the third trimester (n=105, 62%) when all women were
 10 tested. Of the 105 women with anaemia in third trimester, 95 (90%) had iron deficiency anaemia
 11 however, iron treatment was recorded in the electronic health records in less than half of the
 12 anaemic mothers in the third trimester (n = 46, 44%).

13

14 **Table 3. Maternal anaemia screening, prevalence and iron treatment by trimester.**

	n=170
<i>1st trimester</i>	
Hb measured	70 (41)
Anaemic	32 (46)
<i>2nd trimester</i>	
Hb measured	50 (29)
Anaemic	24 (48)
<i>3rd trimester</i>	
Hb Measured	170 (100)
Anaemic	105 (62)
Iron treatment 3rd trimester	46 (44)

15

1 Childhood anaemia screening was high, with more than 146 (86%) children tested at each age
 2 scheduled health check (Table 4). The prevalence of anaemia was considerable across all age groups
 3 with 69 (47%) children diagnosed at six months of age, 75 (50%) at 12 months, 73 (46%) at 18
 4 months and 61 (40%) at 24 months. The prevalence of severe anaemia was higher in those aged six
 5 months when compared with other ages.

6 **Table 4. Childhood anaemia screening and prevalence by age.**

	n=170
<i>6 months</i>	
Hb measured	146 (86)
Anaemia	69 (47)
Severe anaemia	26 (18)
<i>12 months</i>	
Hb measured	150 (88)
Anaemia	75 (50)
Severe anaemia	17 (11)
<i>18 months</i>	
Hb measured	158 (93)
Anaemia	61 (40)
Severe anaemia	8 (5)
<i>24 months</i>	
Hb measured	153 (90)
Anaemia	61 (40)
Severe anaemia	6 (4)

7

8 A full blood count was recorded for 11 children, of which seven results (63%) identified anaemia. All
 9 were hypochromic and microcytic anaemia, suggestive of iron deficiency which was confirmed in
 10 four cases with iron studies.

11 There was a strong positive linear association ($R\text{-square}=0.46$, $p<0.001$) between maternal Hb in
 12 third trimester pregnancy and child Hb at age 6-months (Figure 1). For each 1 g/L change in maternal
 13 Hb there was a 0.6 g/L (95% CI 0.52-0.76) change in infant Hb. The odds of a child developing
 14 anaemia (OR 4.42, 95% CI 2.08 – 9.36) at age six months was four folds greater if their mother had
 15 anaemia in the third trimester of pregnancy compared with those born to non-anaemic mothers
 16 (Table 5). The odds substantially increased if maternal anaemia in third trimester was not treated
 17 (OR 6.17, 95% CI 2.62 – 14.51) however, even with treatment the likelihood of developing anaemia
 18 was still significant (OR 3.00 95% CI 1.25 – 7.17).

1 Maternal anaemia in pregnancy was also associated with an increased odds of childhood anaemia at
 2 age 12 months (OR 2.04, 95% CI 1.03 – 4.06) and 24 months (OR 2.08, 95% CI 1.04 – 4.16) but not 18
 3 months (OR 1.5, 95% CI 0.78 – 2.88). Low birth weight (OR 2.62, 95% CI 1.21 – 5.70) was associated
 4 with childhood anaemia at age six months. The association between prematurity (OR 1.87, 95% CI
 5 0.84 – 4.15) and anaemia at six months did not reach statistical significance.

6
 7 **Figure 1. The association of maternal haemoglobin in third trimester of pregnancy on child**

1 **Discussion**

2 The prevalence of maternal anaemia in pregnancy (62%) in these communities was alarmingly high
3 and not dissimilar to that reported previously (50%) in two large Top End NT communities [1].
4 Maternal anaemia in pregnancy is not routinely reported in the NT Mothers and Babies Report [20]
5 or as a key performance indicator to monitor how well health services are performing for their
6 clients. Further studies would be beneficial to establish how widespread maternal anaemia in
7 pregnancy is in rural and remote Australian Aboriginal communities and to establish the immediate
8 and long term impact of adverse outcomes on maternal and infant health.

9

10 No previous studies have identified the trimester specific prevalence of anaemia among pregnant
11 Australian Aboriginal women. The higher third trimester prevalence in this study may be partially
12 explained by the physiological changes in pregnancy where increased plasma volume leads to lower
13 haemoglobin concentration [21] however, a drop in MCV below normal reference ranges was noted
14 in 84% (n=34) of women who were not anaemic in first trimester, but became anaemic in third
15 trimester, suggestive of depletion of iron stores. The WBM 6th edition [18] identifies that a fall in
16 MCV is the earliest sign of ID however, it does not recommend using this as an indicator for
17 commencing iron supplementation as has been shown in other recent studies [22].

18

19 Maternal anaemia was predominantly IDA (90%) which is recognised as the most common aetiology
20 in pregnancy [23]. The determination of IDA in this study however, was limited by a very small
21 number of iron studies (n = 10) performed and relied on the FBC results of a low Hb with microcytic
22 and hypochromic cells. The recommendation for routine iron studies at the first visit and at 28
23 weeks gestation in the revised WBM 6th edition is a valuable addition [18]. An assessment of iron
24 status will not only be of clinical use for individual women in guiding anaemia prevention and
25 treatment but will provide a more accurate insight into the true contribution of IDA in this
26 population.

27

28 The high prevalence of IDA raises the argument for routine iron supplementation in pregnancy as
29 advocated by WHO in areas with prevalence >40% [24]. Iron supplementation was a
30 recommendation for all pregnant women in the WBMs [25] up until 2014 when conflicting
31 information was printed in the accompanying reference document [26]. Despite the
32 acknowledgement of high anaemia prevalence in Australian Aboriginal women in pregnancy at that
33 time, iron supplementation was not recommended for women who were not anaemic [27]

34

1 The positive effects of iron supplementation at delivery and post-partum do not definitively result in
2 improved maternal and neonatal outcomes except for reducing maternal puerperal infections and
3 preterm births [24]. In this study iron supplementation during pregnancy partially mitigated the
4 effect of maternal anaemia on increased risk of childhood anaemia however iron treatment was only
5 included for the third trimester due to small numbers of treatment recorded in first and second
6 trimesters. Maternal Hb measurements were not adjusted for smoking status in this study due to
7 limited data in electronic health records and may have contributed to an underestimation of
8 anaemia due to falsely elevated Hb in smokers [28].

9
10 Screening for childhood anaemia was high (>86%) at each age scheduled health check and compared
11 favourably to the 80% coverage reported across all remote PHCs [2]. Prevalence of anaemia across
12 all age groups (40-50%) was comparable to that reported in other remote communities across
13 Northern Australia [2]. The assessment of anaemia aetiology in children was limited due to the very
14 small number of FBCs and iron studies performed however, all FBCs and iron studies from anaemic
15 children indicated IDA.

16
17 Children in this age group are further at risk of IDA when they are usually exclusively breastfed,
18 particularly if prolonged before weaning foods are introduced [9]. The recommendation of routine
19 iron supplementation for all exclusively breastfed babies from four months of age in the revised 7th
20 edition CARPA STM was introduced to ameliorate this risk alongside maternal education and
21 availability of iron-rich weaning foods [9]. However, the timing and dosage recommended by the
22 guidelines were not evidenced based and not supported by NT health practitioners.

23
24 Maternal anaemia in the third trimester was the most significant perinatal risk factor associated with
25 the development of childhood anaemia at age six months. This finding emulates evidence from
26 international literature that is applicable in the remote Aboriginal context [10-14]. The association
27 with anaemia in the first six months of life is consistent with the findings of De Pee et al. in
28 suggesting that Hb and iron stores in young infants are dependent on maternal factors [11]. The
29 increased risk of anaemia was observed to persist beyond six months of age with a statistically
30 significant association at 12 and 24 months. This supports the results of Nair et al. who reported the
31 effect of maternal anaemia on childhood anaemia up to 56 months [14].

32
33 LBW was associated with an increased risk of childhood anaemia at six months of age and there was
34 a trend towards an association with prematurity. The accuracy of gestational age at birth was limited

1 with few first trimester dating ultrasounds performed (n=60, 35%) and more than one fifth (n = 35,
2 21%) of antenatal records having no last menstrual period. The findings of this study did not take
3 into account other potential contributors to childhood anaemia, including maternal smoking,
4 diabetes in pregnancy, diet, other micronutrient deficiencies or infection which may have
5 confounded results.

6

7 **Conclusion**

8 The evidence that maternal anaemia in pregnancy was the most significant risk factor for childhood
9 anaemia has public health implications for reviewing practice and policy guidelines. A renewed
10 focus should be placed on anaemia screening, prevention and treatment in pregnancy. Current
11 policy and best practice guidelines for children focus exclusively on LBW and infants born premature
12 in their identification of infants at risk. The current practice of administering prophylactic iron
13 supplementation only to children who are born low birth weight or premature would be of greater
14 benefit if expanded to include children born to anaemic mothers.
