**Learning Objectives**

Upon completion of this activity, participants will be able to:

- Distinguish differences in virulence among *Burkholderia pseudomallei bimBm* sequence variants, based on a mouse model of neurologic melioidosis
- Distinguish differences in progression among *B. pseudomallei bimBm* sequence variants
- Determine the implications for clinical disease of these differences among *B. pseudomallei bimBm* sequence variants in progression and severity of experimental melioidosis.

Neurologic melioidosis is a serious, potentially fatal form of *Burkholderia pseudomallei* infection. Recently, we reported that a subset of clinical isolates of *B. pseudomallei* from Australia have heightened virulence and potential for dissemination to the central nervous system. In this study, we demonstrate that this subset has a *B. mallei*-like sequence variation of the actin-based motility gene, *bimA*. Compared with *B. pseudomallei* isolates having typical *bimA* alleles, isolates that contain the *B. mallei*-like variation demonstrate increased persistence in phagocytic cells and increased virulence with rapid systemic dissemination and replication within multiple tissues, including the brain and spinal cord, in an experimental model. These findings highlight the implications of *bimA* variation on disease progression of *B. pseudomallei* infection and have considerable clinical and public health implications with respect to the degree of neurotropic threat posed to human health.

*B. pseudomallei*, the etiologic agent of glanders, is thought to have evolved from a single strain of *B. pseudomallei*, becoming highly specialized for intracellular persistence (1). *B. mallei* and *B. pseudomallei* share sequence similarity and are highly pathogenic through the respiratory route, often initiating rapid disease progression resulting in high mortality (2). Unlike *B. pseudomallei*, *B. mallei* has a narrower host range and is less capable of extended persistence in the environment.

Knowledge of the virulence factors responsible for inducing the diverse spectrum of clinical manifestations of *B. pseudomallei* infection remains limited (3). Similar to bacteria of other genera, such as *Listeria, Rickettsia, Mycobacterium*, and *Shigella*, intercellular and intracellular movement of *Burkholderia* are facilitated by actin polymerization at 1 pole of the bacterium (4). The putative autotransporter protein *Burkholderia* intracellular motility A (*BimA*) has been shown to mediate actin-based motility in *B. pseudomallei* and *B. mallei*, promoting bacterial dissemination while shielding the pathogen from immune surveillance and autophagy (5). Differences in the structure of the *bimA* gene in *B. mallei* and *B. pseudomallei* (6–8) suggest that actin assembly might occur through distinct mechanisms in these 2 *Burkholderia* species. *B. mallei*-like *bimA* variants (*bimA* 

\[ \text{virulence genes of } B. \text{ pseudomallei} \] with clinical presentations of melioidosis identified the *bimA* allele as a risk factor for neurologic melioidosis (12). Given the importance of *BimA* in intercellular and intracellular spread of *Burkholderia* spp. and the recognition of *bimA* variants of *B. pseudomallei* in northern Australia, we hypothesized that *bimA* variants of *B. pseudomallei* would have an increased advantage for establishment of infection and dissemination compared with typical *bimA* strains. Therefore, we used a well-characterized animal model of melioidosis to compare virulence and disease progression after infection with clinical isolates of *B. pseudomallei* collected in the Northern Territory of Australia during October 1989–October 2012 and identified as having either the *bimA* or *bimB* allele (13).

**Methods**

**B. pseudomallei** Isolates

*B. pseudomallei* strains were isolated from patients with melioidosis. Clinical details and the sequence type determined from multilocus sequence typing of the *B. pseudomallei* strains investigated are noted (Table). Additional details are described elsewhere (11,12,14,15). These isolates were chosen to represent *B. pseudomallei* strains previously identified as having *bimA* (n = 7) and *bimB* (n = 8) alleles within the *bimA* gene (10,12).

Animal Infection

We used 8- to 12-week-old C57BL/6 and BALB/c mice purchased from the Small Animal Breeding Facility at James Cook University. Experiments were approved by the Institutional Animal Ethics committee (A1500). To mimic natural routes of infection, intranasal or subcutaneous routes were used for inoculation by using methods described previously (16). *B. pseudomallei* isolates were cultured to logarithmic phase and prepared for inoculations as previously described (11).

Virulence Determination

Virulence of *bimA* (n = 7) and *bimB* (n = 6) isolates were compared in mice as described previously (11). The 50% infectious dose (ID$_{50}$) was determined by using a modified version of the Reed and Meunch method (17). Virulence, as defined by the ID$_{50}$ values for *B. pseudomallei* strains, were compared in BALB/c and C57BL/6 mice after intranasal and subcutaneous infection. Data for *bimA* and *bimB* strains are expressed as mean log$_{10}$ ID$_{50}$ ± SD.

Bacterial Dissemination and Disease Progression

We selected *bimA* (MSHR543) and *bimB* (MSHR305) strains of comparable virulence (determined by intranasal ID$_{50}$ values as 2.6 × 10$^6$ CFU and 2.9 × 10$^6$ CFU,
isolates in leukocytes was B. pseudomallei isolates were grown to loga

rate for each isolate determined. Data are presented as the mean gradient (μhr) ± SD for bim_148 and bim_286 strains.

### Internalization and Persistence of Bacteria in Phagocytic Cells

We determined internalization and intracellular persistence of B. pseudomallei isolates (n = 7 bim_868; n = 8 bim_243) in mononuclear phagocytes after co-culture with murine leukocytes. Leukocytes were isolated from spleen and peripheral lymph nodes (cervical, mediastinal, axillary, inguinal, and popliteal) of uninfected female C57BL/6 mice (18). B. pseudomallei isolates were grown to logarithmic phase, washed then added to leukocyte cultures at a multiplicity of infection of 1 (mononuclear cell): 5 (bacteria) (19). After 2 hours of co-culture, kanamycin (250 μg/mL) was added to wells to limit extracellular bacterial growth (18). Internalization (2 h) and persistence (8 and 24 h) of B. pseudomallei isolates in leukocytes was determined by flow cytometry. Uninfected and B. pseudomallei–infected leukocytes were fluorescently stained with a combination of anti-mouse fluorescein isothiocyanate–conjugated CD45 and F4/80 (BD Biosciences, North Ryde, NSW, Australia) and peridinin chlorophyll-cyanine 5.5 (PerCP-Cy5.5)–conjugated CD11c (eBioscience, San Diego, CA, USA) by using methods described previously (18). After fixation and permeabilization, leukocytes were stained with polyclonal rabbit anti–B. pseudomallei outer membrane protein antibody (BpOMP). A secondary biotinylated goat anti-rabbit IgG (Vector Labs, Burlingame, CA, USA) monoclonal antibody and streptavidin–phycoerythrin conjugate (eBioscience) was used for

### Bacterial Growth Rate

The growth of B. pseudomallei isolates in trypticase soy broth (TSB) was compared. Overnight broth cultures of B. pseudomallei isolates were diluted 1:10 in fresh TSB and incubated in triplicate at 37°C with shaking at 120 rpm. Absorbance (600 nm) was measured hourly for 10 hours with a microplate reader (Fluostar Omega; BMG Labtech, Mornington, VIC, Australia) and the exponential growth rate for each isolate determined. Data are presented as the mean gradient (μhr) ± SD for bim_868 and bim_243 strains.

respectively) for comparison of bacterial dissemination after intranasal infection of C57BL/6 mice. C57BL/6 mice provide a more accurate model for neurologic melioidosis because this form of the disease tends to occur in otherwise healthy persons without known risk factors (13). MSHR543 (bim_148) was isolated from a localized skin infection in a healthy 22-year-old with a cut on her hand that was exposed to muddy water. Blood cultures were negative, and she remained systemically well with no evidence of dissemination of B. pseudomallei. The bim_868 (MSHR305) strain was isolated from a patient with a fatal case of neurologic melioidosis. The 64-year-old patient had a history of excessive alcohol consumption and had had onset of flaccid paralysis after a period in influenza-like illness (14). An equivalent dose of MSHR543 (1.4 × 10⁴ CFU) or MSHR305 (1.1 × 10⁴ CFU) was used to inoculate mice. Survival rates and signs of disease were monitored daily for a period of 21 days (n = 10 mice per isolate). Mice that became moribund during the experimental period were euthanized, and bacterial loads were determined in organs and pathology of CNS investigated. Parallel groups of mice were inoculated with MSHR543 (bim_148) (n = 15) and MSHR305 (bim_868) (n = 15) for assessment of bacterial loads within blood, liver, spleen, lung, cervical lymph node, brain, and nasal-associated lymphoid tissue (NALT) at 2 hours, 1 day, and 3 days postinfection (n = 5 mice per time point) by using methods described previously (11). The detection limit of bacteria in blood and organs was 2 CFU. Data are expressed as the mean log₁₀ CFU ± SD.

### Bacterial Growth Rate

The growth of B. pseudomallei isolates in trypticase soy broth (TSB) was compared. Overnight broth cultures of B. pseudomallei isolates were diluted 1:10 in fresh TSB and

detection of the primary antibody. Acquisition (2 × 10^5 leukocytes) was performed by using a FACSCalibur with Cell Quest software (BD Biosciences) and FlowJo software (Tree Star, Inc., San Carlos, CA, USA) was used for postacquisition analysis. The fluorescence of extracellular bacteria was quenched with Trypan blue (0.2%). Data are expressed as the percentage or total number of leukocytes (CD45^+^), macrophages (F4/80^+^), or dendritic cells (CD11c^+^) positive for intracellular BpOMP staining. Two independent experiments were conducted, and the mean ±SD of data from both experiments is shown. Microbiologic culture was used to confirm intracellular *B. pseudomallei* numbers estimated by BpOMP staining (20).

**Statistical Analysis**

We performed statistical analysis by using Graphpad Prism Version 6 (Graphpad Software, La Jolla, CA, USA) and used Kaplan–Meier survival curves to compare susceptibility to infection with *B. pseudomallei* isolates. Virulence parameters (ID$_{50}$ values, time for development of neurologic symptoms, and intracellular bacterial loads within leukocytes) for *bim*$_{Bm}$ and *bim*$_{Bp}$ strains were compared by using the Mann-Whitney U test. Bacterial load kinetics in organs after infection with MSHR543 (*bim*$_{Bm}$) and MSHR305 (*bim*$_{Bp}$) were tested for significance using 2-way analysis of variance with Sidak’s post hoc analysis. We considered comparisons significant at p<0.05.

**Results**

**High Virulence of *Bim*$_{Bm}$ Variants in Murine Models of Melioidosis**

We compared virulence, as defined by ID$_{50}$, for *bim*$_{Bm}$ and *bim*$_{Bp}$ strains in *B. pseudomallei*–susceptible (BALB/c) and *B. pseudomallei*–partially resistant (C57BL/6) mice after intranasal and subcutaneous infection (16,21). *B. pseudomallei* *bim*$_{Bm}$ strains were significantly more virulent for BALB/c and C57BL/6 (Figure 1, panels A and B) mice than *bim*$_{Bp}$ strains, regardless of route of infection. These

![Figure 1](https://example.com/figure1.png)

**Figure 1.** Virulence of *bim*$_{Bm}$ and *bim*$_{Bp}$ *Burkholderia pseudomallei* isolates. Day 21 50% infectious dose values after intranasal and subcutaneous infection of BALB/c (A) and C57BL/6 (B) mice with *bim*$_{Bm}$ (n = 7) and *bim*$_{Bp}$ (n = 6) *B. pseudomallei* isolates. Groups of 5 mice were inoculated via intranasal and subcutaneous routes at 10-fold increasing doses of *B. pseudomallei*, ranging from 10^0 CFU to 10^7 CFU. Virulence of *bim*$_{Bm}$ isolates was significantly greater for both mouse strains, regardless of the infection route. Data are expressed as mean log$_{10}$ CFU ±SD. C57BL/6 mice (n = 10) were infected with *bim*$_{Bm}$ (n = 7) and *bim*$_{Bp}$ (n = 6) *B. pseudomallei* isolates at equivalent doses (10^4 CFU) and monitored for 21 days postinfection. The percentage of mice for a given bacterial strain for which evidence indicated establishment of *B. pseudomallei* infection (culture-positive growth from tissues) (C) and signs of neurologic involvement (e.g., head tilt, spinning behavior, and hind leg paresis) (D) was increased for animals exposed to *bim*$_{Bm}$ compared with *bim*$_{Bp}$ isolates. *p<0.05; **p<0.01.
findings are consistent with the BALB/c–C57BL/6 model of contrasting resistance to B. pseudomallei (21).

When equivalent inoculating doses of B. pseudomallei strains were compared (10^4 CFU), bim_{Bp} strains were more likely to establish persistent infection with bacteria recoverable from multiple organs at 21 days postinfection after intranasal infection of C57BL/6 mice (p = 0.077) (Figure 1, panel C). Additionally, neurologic involvement occurred with more frequency in animals infected through the intranasal route with bim_{Bm} compared with those infected with bim_{Bp} strains when an equivalent inoculating dose (10^4 CFU; n = 10 mice/B. pseudomallei strain) was used (p = 0.046) (Figure 1, panel D). Most B. pseudomallei strains tested were capable of CNS infection; however, neurologic involvement tended to occur at comparatively lower inoculating doses for bim_{Bm} than bim_{Bp} strains. The mean number of bacteria required to infect susceptible BALB/c mice via the respiratory route and manifest neurologic signs in ≥20% of mice was 8.6 × 10^4 CFU (range 5.3 × 10^4 to 2 × 10^5 CFU) for bim_{Bm} and 3.7 × 10^4 CFU (range 2.6 × 10^4 to 6.6 × 10^4) for bim_{Bp} (p = 0.048). Despite infection of C57BL/6 mice with doses as high as 10^5 CFU, neurologic symptoms were never observed after infection with 2 strains (MSHR3709 and MSHR1655), both of which are type bim_{Bm}.

The mean number of bacteria required to infect susceptible BALB/c mice via the respiratory route and manifest neurologic signs in ≥20% of mice was 8.6 × 10^4 CFU (range 5.3 × 10^4 to 2 × 10^5 CFU) for bim_{Bm} and 3.7 × 10^4 CFU (range 2.6 × 10^4 to 6.6 × 10^4) for bim_{Bp} (p = 0.03). For C57BL/6 mice, the mean number of days postinfection for onset of neurologic symptoms was 9 (range 5–16) days; for BALB/c mice, it was 11 (range 4–18) days. These findings indicate that bim_{Bm} variants are significantly more virulent than bim_{Bp} strains in murine models of melioidosis and suggest that fewer inoculating bacteria are required to establish CNS infection.

Differing Disease Progression for bim_{Bm} and bim_{Bp} Strains after Intranasal Infection
We selected a bim_{Bm} (MSHR543) and bim_{Bp} (MSHR305) strain of comparable virulence to compare organ tropism after intranasal infection (intranasal ID_{50} values of 2.6 × 10^2 and 2.9 × 10^2 CFU, respectively). Twenty-one day mortality rates were comparable after intranasal infection with either MSHR543 (bim_{Bm}) or MSHR305 (40% and 50%, respectively). However, of the animals monitored for survival, 2 of the 5 mice that succumbed to infection with MSHR305 (bim_{Bp}) had neurologic symptoms (1 with head tilt on day 7, another with hind limb paresis on day 14). In contrast, all of the 4 mice that succumbed to infection with MSHR543 (bim_{Bm}) had symptoms of neurologic melioidosis (3 with head tilt on day 5 and day 7, the other with hind paresis on day 7). Moribund mice were euthanized and tissues processed for bacterial load determination. Bacterial loads were high in brains of moribund mice (Figure 2). B. pseudomallei was typically recovered from all tissues investigated, although levels tended to be low or undetectable in the blood of moribund mice that had signs of neurologic infection in the first week postinfection. Compared with moribund animals infected with MSHR543 (bim_{Bm}), bacterial loads were significantly higher in NALT of moribund mice infected with MSHR305 (bim_{Bp}; p = 0.025), with a similar trend observed in lung. Abscessation was observed in the nasal epithelium, with extensive suppurative inflammation in the olfactory submucosa extending to the olfactory bulb and moderate infiltration in the trigeminal nerve branches (Figure 3, panels A and B) in mice that had signs of neurologic involvement at day 5 postinfection with MSHR543 (bim_{Bm}). Leptomeningitis and encephalomalylitis were cardinal features in these animals (Figure 3, panels C and D). We also observed cranial microabscesses were in animals that succumbed to infection, although the area affected varied and included the cerebellum, brainstem, and cerebral cortex (Figure 3, panel E).

Systemic dissemination occurred rapidly for MSHR543 (bim_{Bm}) and MSHR305 (bim_{Bp}); bacteria were recovered from multiple sites by day 1 postinfection (Figure 4). At 2 hours postinfection, NALT was the only tissue that bacteria were cultured from, with levels comparable for mice infected with MSHR543 (bim_{Bm}) and MSHR305 (bim_{Bp}) (log_{10} CFU of 0.9 ± 1.1 and 0.3 ± 1.1, respectively). Compared with

![Figure 2. Brain bacterial loads in mice that had signs of neurologic involvement and succumbed to infection with MSHR543 (bim_{Bm}) and MSHR305 (bim_{Bp}) Burkhodleria pseudomallei isolates. Bacterial loads in brains of C57BL/6 mice (MSHR543, n = 4; MSHR305, n = 5) that had become moribund and required euthanasia within the 21-day experimental period after intranasal infection with MSHR543 (1.4 × 10^4 CFU; white bars) and MSHR305 (1.1 × 10^4 CFU; black bars). N indicates mice that displayed symptoms of neurologic involvement. Data are expressed as log_{10} CFU. Mice exposed to MSHR543 (bim_{Bm}) had signs of neurologic involvement and became moribund within 7 days of exposure.](http://www.cdc.gov/eid/)
Increased Threat from *B. pseudomallei*, Australia

MSHR305 (*bim*<sub>Bp</sub>), replication of MSHR543 (*bim*<sub>Bm</sub>) was significantly higher in cervical lymph nodes and spleen (Figure 4). Bacterial loads were low in brains of mice infected with MSHR543 (*bim*<sub>Bm</sub>) and MSHR305 (*bim*<sub>Bp</sub>) within 3 days of infection despite signs of neurologic involvement by day 5 postinfection in 4 mice infected with MSHR543 (*bim*<sub>Bm</sub>), corresponding to bacterial loads in the brain in excess of 10<sup>2</sup> CFU (Figure 2). In comparison, only 1 animal infected with MSHR305 (*bim*<sub>Bp</sub>) had symptoms of neurologic melioidosis and required euthanasia within 7 days.

Five mice (50%) survived to 21 days after intranasal infection with MSHR305 (*bim*<sub>Bp</sub>), of which 4 had evidence of persistent *B. pseudomallei* infection, with bacteria recovered from the brain of 1 mouse (Figure 4, panel C). Six mice (60%) survived after intranasal infection with MSHR543 (*bim*<sub>Bm</sub>), and all had evidence of persistent infection, with bacteria recovered from the brains of 5 mice (Figure 4, panel C).

These findings demonstrate that despite equivalent inoculating doses and similar 21-day mortality rates, the pattern and kinetics of dissemination differ for MSHR543 (*bim*<sub>Bm</sub>) and MSHR305 (*bim*<sub>Bp</sub>) after intranasal infection, with neurologic involvement occurring with more frequency after infection with MSHR543 (*bim*<sub>Bm</sub>).
Increased Persistence of \textit{bim}_{Bm} Strains in Mononuclear Phagocytic Cells

To investigate whether differences observed in systemic dissemination in vivo might be attributable to inherent differences in multiplication of \textit{bim}_Bm and \textit{bim}_Bp strains, we compared the in vitro growth rate of isolates in broth culture. No significant differences were observed for the exponential growth of \textit{bim}_Bm and \textit{bim}_Bp variants in TSB (slope, \(\mu hr^{-1}\), 0.105 ±0.02 and 0.092 ±0.02, respectively). Having demonstrated that \textit{bim}_Bm and \textit{bim}_Bp strains multiply at the same rate in cell-free media, we next investigated whether intracellular growth rates were comparable for the 2 groups of isolates. Because macrophages and dendritic cells play a pivotal role in protection against \textit{B. pseudomallei} infection (3), we compared the uptake and persistence of \textit{bim}_Bm (n = 7) and \textit{bim}_Bp (n = 8) isolates in ex vivo cultures of murine spleen and lymph node–derived macrophages and DC. Absolute numbers of leukocytes were comparable for \textit{bim}_Bm– and \textit{bim}_Bp–infected cultures at 2, 8, and 24 hours postinfection (Figure 5, panel A). The percentage of leukocytes positive for BpOMP staining was also comparable in cultures infected with \textit{bim}_Bm and \textit{bim}_Bp strains at 2 and 8 hours postinfection (Figure 5, panel B). However, by 24 hours, the proportion of BpOMP–leukocytes was significantly higher in cultures infected with \textit{bim}_Bm than \textit{bim}_Bp strains (\(p = 0.002\)), and persistence of \textit{bim}_Bm isolates was greater in CD11c+ dendritic cells (\(p = 0.012\)) and F4/80+ macrophages (\(p = 0.006\)) than \textit{bim}_Bp strains (Figure 5, panel C). Overall, these data suggest that \textit{bim}_Bm strains of \textit{B. pseudomallei} might possess mechanisms to facilitate their internalization and intracellular persistence within professional phagocytes.

Discussion

Although uncommon, neurologic melioidosis is a severe and debilitating form of \textit{B. pseudomallei} infection, primarily affecting healthy persons with no recognizable risk factors and occurring with increased frequency in Australia (13,14,22). Diagnosis and management of neurologic melioidosis is challenging because of nonspecific clinical presentation, poor diagnostics, and intrinsic resistance to antibiotics. Similar to other intracellular bacteria, \textit{B. pseudomallei} and \textit{B. mallei} are able to spread to adjacent host cells and evade immune surveillance through the formation of actin tails in a process that involves polymerization of host actin monomers (5,10,23,24). Polymorphisms in machinery used for actin assembly in other obligate intracellular bacteria have been reported to influence virulence and tissue tropism (25–27). Recently, isolates possessing a \textit{B. mallei}–like \textit{bim}A allele (\textit{bim}_Bm) were shown to be associated with neurologic involvement in human melioidosis (12). Our study provides in vivo evidence of the implications of the \textit{bim}_Bm sequence variation on disease progression and severity of experimental melioidosis. Compared with \textit{B. pseudomallei} isolates with typical BimA motifs, \textit{bim}_Bm variants were more virulent in an animal model of melioidosis when delivered intranasally or subcutaneously. This subset of strains was associated with increased persistence within phagocytic cells and increased likelihood of establishing CNS infection compared with \textit{bim}_Bp strains of \textit{B. pseudomallei}.

Although no evidence from our study indicates preferential seeding of the CNS compared with other tissues, CNS infection did occur with increased frequency and at lower inoculating doses after infection of mice with \textit{bim}_Bm than \textit{bim}_Bp strains of \textit{B. pseudomallei}. Neurologic involvement was observed after intranasal and subcutaneous inoculation with \textit{B. pseudomallei} isolates, although the frequency of CNS infection increased after intranasal infection. Neurologic involvement, as evidenced by bacterial colonization of the brain

---

**Figure 5.** Internalization and persistence of \textit{bim}_Bm and \textit{bim}_Bp \textit{Burkholderia pseudomallei} isolates within murine leukocytes. Spleen and lymph node–derived leukocytes were co-cultured with \textit{B. pseudomallei} isolates at multiplicity of infection 1:5. A) At 2, 8, and 24 hours postinfection, absolute numbers of CD45+ leukocytes were comparable in cultures infected with \textit{bim}_Bm and \textit{bim}_Bp strains. B) Bacterial uptake (2 h) and persistence (8 h and 24 h) was compared by assessing the percentage of CD45+ leukocytes that were positive for intracellular \textit{B. pseudomallei} outer membrane protein antibody (BpOMP) staining using flow cytometry. BpOMP staining increased within leukocytes between 8 hours and 24 hours of cultures. Compared with \textit{bim}_Bm, the percentage of leukocytes positive for intracellular BpOMP was significantly higher in cultures stimulated with \textit{bim}_Bm isolates at 24 hours postinfection. Internalization of \textit{bim}_Bm or \textit{bim}_Bp isolates by CD11c+ dendritic cells and F4/80+ macrophages was comparable (not shown). C) However, persistence of \textit{bim}_Bm strains was significantly higher in dendritic cells and macrophages after 24 hours of culture. Data reflect the mean ±SD of 2 independent experiments. BpOMP, \textit{B. pseudomallei} outer membrane protein antibody; DC, dendritic cells; MΦ, macrophages. *\(p<0.05\); **\(p<0.01\); ***\(p<0.001\).
and neutrophil infiltration to the cranial and spinal meninges, occurred with more frequency in animals infected with MSHR543 (bim<sub>bim</sub>) than those exposed to MSHR305 (bim<sub>bim</sub>). Although we observed considerable variability in the sites of abscessation in the CNS, leptomenigitis, meningoencephalitis, and encephalomylitis were common features in animals that succumbed to infection. Similar neuropathology has been reported in experimental models using intravenous (rather than intranasal) challenge of mice with *B. pseudomallei* (28). Furthermore, the neuropathology observed in our study is consistent with the only published histopathologic study of human CNS from patients with melioidosis encephalomylitis (14).

Clinical and experimental data suggest *B. pseudomallei* is capable of using ≥1 mechanism for entry into the brain and spinal cord (28–37). *B. pseudomallei* has been shown to take advantage of olfactory and trigeminal nerve branches to gain direct access to the brain after respiratory infection of mice (29–32), and St. John et al. (32) recently demonstrated a role for bim<sub>A</sub> in direct CNS invasion by *B. pseudomallei*. Clinical reports also support progression of sinusitis or upper respiratory tract infection with *B. pseudomallei* to neurologic melioidosis (33–35). Additionally, cortical brain abscesses, a clinical presentation commonly reported for neurologic melioidosis in Southeast Asia (33), were observed and are consistent with bacteremic spread of *B. pseudomallei*, directly or through transmigration of infected leukocytes, to the CNS (28). In addition to direct infection through the upper respiratory tract, cases of neurologic melioidosis from the Darwin Prospective Melioidosis Study have recently provided strong support for direct brainstem or spinal cord infection occurring through nerve root translocation of bacteria secondary to skin inoculation with *B. pseudomallei* on the face/scalp or limbs (36,37). The observation of hind leg paraparesis in some animals after *B. pseudomallei* infection in our study provides additional support for this postulated mechanism of CNS entry.

In our study, rapid systemic dissemination to secondary lymphoid tissues was observed for *B. pseudomallei* bim<sub>bim</sub> and bim<sub>bim</sub> variants, with significantly higher bacterial loads observed earlier in these tissues after infection with the bim<sub>bim</sub> variant. Moreover, despite significant reduction in intracellular bacterial loads, persistence of *B. pseudomallei* was evident in vitro in dendritic cells and macrophages, tissue phagocytic cells that *B. pseudomallei* would be exposed to in the early stages of subcutaneous and intranasal infection. We acknowledge that other leukocyte subsets might support intracellular infection with *B. pseudomallei* and therefore potentially contribute to rapid dissemination of this bacterium in vivo. We limited our assessment to dendritic cells and macrophages because these cells are among the earliest responders to infection and are critical for controlling *B. pseudomallei* infection (3,20,21). Skin dendritic cells also migrate to secondary lymphoid tissues, facilitating the trafficking and systemic dissemination of live intracellular *B. pseudomallei* (18). Our data support a potential role for professional phagocytic cells in rapid systemic dissemination of *B. pseudomallei* to distant sites such as the CNS.

As an increasing number of clinically derived strains are genotyped, it is becoming apparent that the manifestations of melioidosis are likely to be influenced by the infecting strain, as well as the route of infection, infecting dose, and host risk factors for melioidosis. Our findings from this current study provide strong support to our clinical observations (12) that bim<sub>bim</sub> variation is a predictor for severe forms of melioidosis, including neurologic involvement. Despite comparative interrogation of genomes between *B. pseudomallei* strains of contrasting virulence (38,39), to date bim<sub>A</sub> has been identified as the only gene with a strong association with neurologic melioidosis. However, our observation that bim<sub>bim</sub> strains have the potential to invade the CNS, albeit typically at higher inoculating doses than bim<sub>bim</sub> strains, suggest that genes other than bim<sub>A</sub> also contribute to *B. pseudomallei* invasion and dissemination in vivo. Under favorable circumstances, avirulent *B. pseudomallei* strains and even the closely related but avirulent bacterium, *B. thailandensis*, can initiate systemic and lethal infection (40,41). Identifying and characterizing bacterial effector proteins involved in the intracellular and intercellular spread and persistence of *B. pseudomallei* and *B. mallei* will be critical for identification of novel agents to manipulate these processes with therapeutic application.
